

Description

Helical device to convert potential to mechanical energy

Appendix Data

[0001] Definitions Appendix_A

Generally cylindrical - Describes a housing with radial symmetry but where the radius measurement may vary along the axial length. I.e., the housing may include tapers, bulges etc.

Helical baffles - Describes a fin-like construction from the inside of the housing toward the axis of the housing. The baffles will be generally sealed to the housing however some weep holes, access points etc. may be incorporated. A version whereby the baffles are semi-sealed but not physically connected to the housing is also claimed. The pitch of the helix may be varied along the axial length of the housing. The profile of the baffle (the cross section formed by a plane containing the housing axis and any radius) may be of a curved nature to maximize the fluid capacity, minimize frictional losses, fluid turbulence or otherwise improve the efficiency of the device.

AquaHelix - Proprietary term, September 2003 search indicates it is not US Copyrighted as of that time, used to describe the mechanism contained in this patent.

Sealed – The term sealed shall be taken to mean allowing minimal leakage of a fluid barrier in relation to the volume of fluid associated with the device. While the seal will generally be accomplished by solid materials, other form of seals allowing relative motion of portions of the barrier may be utilized and some degree of leakage may be expected or intentionally designed.

Background of Invention

[0002] Field of the Invention

The field of the invention is that of methods and apparatus for converting the energy of fluid mass at elevation into kinetic energy in the process of conveying the fluid to a lower elevation. One specific benefit of which would be the subsequent generation of electricity from said kinetic energy such as that accomplished in hydroelectric power generation.

[0004] Description of Related Art:

[0003] Of commercial high capacity renewable energy sources, water has the longest history, is the most easily harnessed and has the best potential for an environmentally friendly source of energy. The invention is intended to provide a preferred device for use in hydroelectric mechanisms for the conversion of potential energy in the water to mechanical energy. This energy would then be used to power electrical generation equipment or put to other productive use. The alternative methods to accomplish this that are currently in place include but are not limited to: turbines, water wheels, hydraulic ram pumps, wave and tidal capture and other mechanisms. Each of these has inherent negatives, many of which are addressed in AquaHelix, the mechanism herein described. The device herein has the potential for retrofit in existing hydroelectric dams and well as in new construction and smaller personal installations. The simplicity of

this device may make the cost and effort of operation appealing in situations otherwise unfeasible for conventional technologies

Much of the prior art that has been identified in a patent search has embodied numerous variations of using a blade of some manner (turbine, impeller, vane or wing) similar to a fan, whereby the inertial force of a fluid or gas in motion is impinging against the blade or the Bernoulli effect of passing over the blade results in a force and resulting in motion. The significant differentiation of the device proposed in this patent is that the helical baffles serve only to contain the fluid and no fan-like or wing like effect is present in the device. The development of power is effected from the conversion of elevational potential energy to kinetic mechanical energy as a mass of fluid is lowered from one elevation to a lower elevation. The movement of fluid in 512 is positive displacement in nature as a contained volume of fluid in a baffle area is constrained and lowered as a batch. The small relative amount kinetic energy associated with the gradual lowering of the batch of water is inconsequential to the conversion and capture of the potential energy and in fact there is no mechanism present in 512 to attempt to capture the kinetic component of the energy contained in the fluid. In the evaluation of the numerous prior arts detailed below the reliance on the kinetic energy of a moving stream of fluid is a significant distinction which is described above and is referenced in the subsequent details as "reliance on conversion of kinetic energy"

US Patent 6,327,994 December 11, 2001 - Labrador

This amazing piece encompasses a mass of 127 related claims all of which are dependent claims to Claim number 1 or are dependent to another claim which in turn is dependent on claim one. Claim one states in part to "...imped and to drive moving fluids/air in order to pump/compress and to convert ..." The proposed device described in the 512 application does not purport to extract energy from moving fluids or air and therefore is distinct and cannot be in conflict with the claims of 994.

US Patent 928,782 July 20, 1909 - Morrison

Unlike the device proposed in 512, this device necessitates being placed "in a water course" and deriving energy from the impinging of moving water on an "impact area for causing rotation of the cylinder." This is one of the devices that as described above, "relies on the conversion of kinetic energy" of flowing water, similar to that of putting an impeller in a moving stream. This is significantly distinct from the mechanism in 512 as previously discussed.

US Patent 4,218,175 August 10, 1980 - Carpenter

This device describes a wind turbine and does not apply to fluids, in addition it "relies on the conversion of kinetic energy" from the medium, in this case a gas which is materially different from the mechanism described

in 512.

US Patent 4,272,685 June 9, 1981 - Toyama

This patent describes a variation on a traditional fluid turbine where by fluid in motion is converted by turbines to mechanical energy. Fluid is taken from the "bottom of the dam" and is subsequently converted. This 512 device is not infringing as it does not propose nor would it be possible to utilize an off take at the bottom of a dam and the 685 patent "relies on the conversion of kinetic energy" as previously discussed.

US Patent 4,325,354 April 20 1982 - Fuchs

This patent describes a variable transmission device intended to optimize the speed of a wind driven blade for maximum efficiency. It is non applicable to the 512 device proposed as 512 is a positive displacement device and the ratio of fluid flow to rotational speed is not subject to slippage or optimization in the manor described in 354.

US Patent 4,512,716, April 23, 1985 - McHenry et al.

This patent describes a device to optimize the radial velocity profile of a gas flow into a turbine to optimize efficiency such that the speed of the gases adjacent to the axis is faster than that approaching the radius. As the device described in 512 does not extract energy from the kinetic energy of motion or pertain to the extraction of energy from gases of any form, it is

not subject to infringement of this patent.

[0005] Minimum prior art of this nature has been discovered. The concept utilized in typical cement mixer trucks actually has similar characteristics albeit run in a reverse fashion, and for the purpose of mixing in a closed recycled nature rather than for transport from one elevation to another and for energy conversion.

[0006] A search of prior art in the area of this invention resulted in the following related but differentiated patents. Substantial differences between claims herein and prior art is described below.

[0007] US PTO #6,253,700 covers the use of a helical blade submerged in a fluid flow in an attempt to convert energy. The claims of that patent differ in numerous ways from that covered herein, but most significantly in that the basic concept and design is to convert the kinetic energy of moving fluid to mechanical energy via a foil effect versus the basic design covered herein to extract potential energy from a fluid by a change in elevation into mechanical energy.

[0008] US PTO #4,268,226 covered a scheme whereby the internal volume of a tube is changed by a helical constraint around a pliable tube that causes a

pumping action when the assembly is subjected to distortion. This patent also differs in substantial ways, the greatest of which is the lack of helical baffles that constrain a fluid.

[0009] US PTO #4,465,430 covered a scheme whereby a stationary helix is utilized to impart a swirl motion to fluid prior to entry into a turbine or propeller to improve efficiency of the turbine or propeller. The device claimed herein is not designed to optimize efficiency of a subsequent step such as a turbine or propeller; it is an energy conversion device in its own right.

[0010] US PTO #4,871,304 describes a compressor consisting of a spiral groove and blade along the length of a cylinder, the geometry of the device varies along its length such that the fluid is compressed in volume as it moves from input to output. The device claimed herein is not designed to compress fluid, nor does it rely on the relative motion of internal and external rotating bodies or a blade fitted to a helical groove.

[0011] US PTO #'s 6,253,700 and 6,293,835 describes a plurality of air foil shaped blades to be utilized in conjunction with a ultra low-head fluid in order to extract or impart kinetic energy from or to a fluid or gas. The device claimed herein differs in substantial ways, the most significant of which is

the necessity for a material fluid head and lack of the requirement of air foil shapes blades or material kinetic energy in the fluid or gas.

[0012] US PTO #6,257,855 describes a compressor consisting of a set of helical rotors which intermesh in order to create a positive displacement pump for creation of pressure or vacuum. The device claimed herein differs in substantial ways, the most significant of which is the lack of necessity for dual intermeshing helical rotors.

[0013] US PTO #6,273,673 describes a pump consisting of a helical baffle through which one or more balls are transported resulting in the displacement and transport of the surrounding fluid. The device described herein among numerous differences does not rely on the use of balls in the helical channels.

[0014] No other patents or demonstrations of similar technology have been discovered in USPTO searches or during research and development of this patent.

[0015] Unmet Opportunity in the Industry

[0016] With the recent power shortages, middle eastern oil concerns and national attention to energy costs, this device offers an attractive solution to

harnessing more energy from existing and new hydroelectric generation dams and providing a solution for smaller installations for personal use, industrial use or sale back to the power grid under PUC net metering regulations. The device offers a potentially significant improvement in the conversion efficiency, offering more power from existing installations or the same power from fewer installations.

[0017] With the growing concern over the regrettable killing of fish and marine animals in hydroelectric turbines, this invention will be particularly attractive. It should dramatically reduce this problem by eliminating the high speed under water blades and the small volumes of "uncleaved" water that pass thru the turbines and well as dramatically reducing the turbulence and velocity that the water and wild life are subjected to in traditional turbine installations.

[0018] Brief Summary of the Invention

The device described herein is comprised of a cylinder with an internal helically shaped baffle which produces a series of cavities along the length of the cylinder in the lower half that are capable of containing a fluid. When the device is positioned at a angle from horizontal and a fluid such as water is introduced at the top of the device the resulting forces of the fluid on the helical walls of the cavities creates a torque around the

axis of the cylinder. If the cylinder is then allowed to rotate and fluid is continuously introduced at the top, mechanical energy is generated from the lowering of the fluid in the chambers and can be extracted from the rotation of the cylinder for productive use such as in electrical generation.

Brief Description of Drawings

- [0019] Drawing 1. This drawing portrays the effect of larger and smaller helix pitch on the volume of liquid in the device. Smaller pitch results in higher volume.

- [0020] Drawing 2. This drawing portrays the effect of larger and smaller helix pitch on the spill effect at the exit of the device. Smaller pitch results in less potential energy loss at discharge.

- [0021] Drawing 3. This drawing depicts a baffle cross section with a high volume of water captured in a helix turn.

- [0022] Drawing 4. This drawing portrays a baffle cross section with low surface area of the baffle in contact with the fluid.

- [0023] Drawing 5. This drawing portrays the effect of larger radius and helix pitch at the entrance of the device.

- [0024] Drawing 6. This drawing portrays the effect of larger radius and helix pitch at the exit of the device .
- [0025] Drawing 7. This drawing portrays the design of a bulb shaped entrance utilized a siphon feed technique.
- [0026] Drawing 8. This drawing portrays the change in input elevation via shortening or lengthening of the device and a typical mechanism to allow rotation around the axis while constraining axial motion.
- [0027] Drawing 9. This drawing portrays the change in input elevation via changing the angle of the device.
- [0028] Drawing 10. This drawing portrays a 3 dimensional view of the preferred embodiment of the device.

Detailed Description

- [0029] A helical baffle is enclosed in a generally cylindrical housing such that when the device is oriented on an angle, that open cavities capable of holding a volume of fluid are created in each of the helical turns between the baffle and the interior walls of the cylinder as depicted in figure 10. As the laws of physics allow that in a steady state situation, fluid pressure

applied to a surface acts perpendicular to a tangent of that surface. That portion of the fluid contacting the helix will result in a moment of force around the axis of the cylinder and a component of force in the downward axial direction. A component of force will also be developed in the radial direction if a helical profile is utilized that is non-perpendicular to the axis of the housing. The remainder of the fluid will act on the walls of the cylinder creating additional forces in radial directions. As both radial and axial motion will be constrained by the housing and a thrust bearing, no energy will be extracted from the fluid from these components of force. The remaining rotational or moment forces will result in rotation of the helix and housing (not withstanding claim 8). As the rotational speed is kept relatively low in this device, it will approach steady state conditions as the magnitude of frictional and kinetic forces of the water will be low compared to those forces described above. Said otherwise, the frictional drag of the fluid against the baffle and housing walls will be small as compared to the forces generated by the pressure of the fluid. The resulting force vector will cause the assembly to turn about the cylinder's axis when adequate bearings or other friction reducing mechanism is utilized to allow the device to rotate. The axial vector of force of the fluid as well as the weight of the device itself will simultaneously create a tendency for a downward movement along the cylinder's rotational axis and therefore will require some form of constraint such as a thrust bearing to constrain axial movement.

[0030] Mechanical energy can then be extracted from the rotation of the device either by gearing, belts, frictional or other means from the surface motion of the outside of the housing, or by an axial off take thru the middle of the structure or by other means. This mechanical energy can then be utilized as desired as an energy source for subsequent operations such as electrical generation.

[0031] The improved efficiency of this device verses conventional turbines is derived primarily from the decreased kinetic energy present in the discharge of the fluid and from decreased viscous frictional losses. The basic mechanism of most devices in the hydroelectric realm (a principle focus of this invention) is the conversion of energy from potential energy, mass (water) at an elevation, to residual potential energy, mass at a lower elevation and mechanical energy that can be harnessed and utilized typically for the production of electricity. The efficiency of the conversion to mechanical energy is dependent on the amount of energy lost to other unharnessed forms specifically frictional energy and kinetic energy of the fluid at discharge. Frictional energy ultimately shows itself as heat, either in the mechanism, the air or in the fluid. Kinetic energy is attached to and wasted in the form of mass in motion of the fluid at the discharge of the device. The relative magnitude of energy in each of these forms is calculated below and is instructive to see the potential savings of the

described device. As the speed of revolution of the device is slowed to approach 0, so does the loss to kinetic energy and the loss to viscous friction (heat gain) of the fluid. The calculation below is instructive as to the magnitude of potential gains from the device. The calculations below demonstrate that in a typical hydroelectric turbine installation, that for every 100 tons of water and every 100 foot of elevation, there exists the potential energy of 7.53 Kilowatt-hours of energy. With a typical discharge water speed of 20 miles per hour, 1.01 Kilowatt-hours of energy is wasted in the form of kinetic energy and with a 1/10 degree Fahrenheit increase in temperature an additional 1.48 Kilowatt-hours of energy is consumed to heat the water and cannot be captured for productive use. This results in a maximum potential capture of energy of 5.04 of the original 7.53 Kilowatt-hours of energy or 67% efficiency. The device described herein has materially less exit fluid velocity and shearing friction resulting in fluid heating. The result is a potential increase in overall efficiency of up to 49% (33/67)from the energy lost it in exit velocity and temperature alone

[0032] The potential energy in 100 tons of water at 100 ft is 7.53 KW-hours as calculated below

$$\text{Joules (energy)} = \text{mass in kg} * 9.81 \text{ m/sec}^2 \text{ (gravity)} * \text{height in m}$$

$$100 \text{ tons} * 907.185 \text{ kg/ton} = 90718.5 \text{ kg}$$

$$100 \text{ ft} * .3048 \text{ m/ft} = 30.48 \text{ m}$$

$$\text{Substituting: } 90718.5 \text{ kg} * 9.81 \text{ m/sec}^2 * 30.48 \text{ m} = 27,126,000 \text{ Joules}$$

$$27,126,000 \text{ Joules} / 3,600,000 \text{ Joules/KW-hour} = 7.53 \text{ Kilowatt-hours}$$

[0036] The kinetic energy in 100 tons of water traveling at 20 mph is 1.01KW-hours as calculated below

$$\text{Joules(energy)} = \frac{1}{2} * \text{mass in kg} * (\text{velocity in m/s})^2$$

$$100 \text{ tons} * 907.185 \text{ kg/ton} = 90718.5 \text{ kg}$$

$$20 \text{ mph} * (.44704 \text{ (meters/sec)} / \text{mph}) = 8.9408 \text{ m/s}$$

$$\text{Substituting: } \frac{1}{2} * 90718.5 \text{ kg} * (8.9408 \text{ m/s})^2 = 3,626,000 \text{ joules}$$

$$3,626,000 \text{ joules} / (3,600,000 \text{ Joules/KW-hour}) = 1.01 \text{ Kilowatt-hours}$$

[0040] 100 tons of water raised .1 degree Fahrenheit from viscous friction absorbs 1.48 Kilowatt-hours of energy

$$\text{Gram-degree C(energy)} = \text{mass(grams)} * \text{change in Temp. (degree C)}$$

$$100 \text{ tons} * 907,184 \text{ grams/ton} = 90,718,400 \text{ grams}$$

$$.1 \text{ degree F} * 5/9 \text{ degree C} / \text{degree F} = .055556 \text{ Degree C}$$

$$\text{Substituting: } 90,718,400 \text{ grams} * .055556 \text{ Degree C} = 5,039,951 \text{ gram-degree C}$$

$$5,039,951 \text{ gram-deg C} * .29307 \text{ watt-hr/BTU} = 1,477,058 \text{ watt-hrs}$$

$$1,477,058 \text{ watt-hrs} = 1.48 \text{ KW-hrs}$$

[0044] While a 20 mph discharge speed and .1 degree F discharge water temperature gain are crude estimates of typical turbine hydroelectric installations, the benefit of reductions in these areas are significant, the combined losses of 2.49 Kilowatt-hours being 1/3 of the potential energy (7.53 Kilowatt-hours) that could be obtained. The temperature change, while real in concept has the further complication of an evaporative cooling effect that becomes significant in the turbulent discharge of traditional hydroelectric dams where portions of the wasted kinetic energy hasten evaporative heat transfer and result in re-cooling the water, potentially cooler than the entrance temperature. However, despite this countering effect on the water temperature, the viscous losses due to high turbulence and turbine shear are no less wasteful in traditional hydroelectric turbine technology. As the size of the AquaHelix carrying a given volume increases the rpm of the device decreases and as the rpm approaches zero the kinetic and viscous frictional losses also approach zero. An optimization of the higher cost of construction and the frictional losses in the larger device itself countered by the lower kinetic and viscous frictional losses would be utilized to size the device and determine the optimal operating rpm.

[0045] The helix pitch of the baffle can also be optimized to maximize the net power obtained. This would be accomplished by lab modeling and measurement of the net rotational energy obtained from various pitches for a given fluid and housing diameter. As the helix pitch is decreased, more turns, the total fluid volume and therefore conversion potential contained in the device at any point in time would increase (See Drawing 1). In addition the lost potential energy due to the spilling effect at the exit would also be reduced (See Drawing 2). However, as the helix pitch is decreased surface area exposed to a given amount of fluid is increased and therefore the viscous frictional losses are larger. Weight of a lower pitch device would also be increased and thereby increasing the losses to friction in the rotational and thrust bearing surfaces. The optimal pitch will be a function both of the fluid characteristics and the diameter of the housing as well as the cross section of the baffle as discussed below

[0048] The cross section of the baffle can also be optimized to maximize the net power obtained. This would be accomplished by optimizing the baffle design to carry more fluid per turn of the helix versus the viscous fluid losses of various cross sections. A cross section with base parallel to the fluid surface (horizontal) and a minimal interior radius would increase fluid per turn of the helix (See Drawing 3). However, the ratio of fluid volume to surface in contact with the housing and baffle can also be optimized for various angles of the baffle (See Drawing 4). The optimal design will be a compromise between these two extremes that provides the

maximum net power obtained for a given fluid and housing characteristics. The exact profile of the baffle will be optimized through lab and prototype experimentation.

[0049] The radii of the housing as well as the radii and pitch and baffles may vary along the axial length of the device in order to further optimize the conversion of energy or for physical design considerations, for example:

[0050] 1. The top, input end of the device may be of increased radius and helix pitch in order to better accept the inflow of fluid. With a larger radius and pitch fluid can be entered more easily and the average "drop" of fluid which wastes energy to kinetic and heat forms can be minimized as the depth of the fluid going into the device would be lessened (See Drawing 5) thus reducing loss potential energy associated with introduction of fluid into the device.

[0051] 2. The bottom, exit end of the device, may also be increased in diameter and pitch to decrease the inefficient spill at the exit as well as extracting some of axial direction kinetic energy from the fluid by slowing the exit velocity (See Drawing 6).

[0052] 3. A bulb shaped top, input end, may also be utilized with a siphoning configuration to provide for an effective sealing effect between the source

of the fluid and the conversion device (See Drawing 7). This concept has potential additional advantages of allowing the supply reservoir to be somewhat remote from the device. This could potentially be upstream of an area of rapids where the accumulated elevation fall is adequate for power generation but where no individual "fall" is of sufficient elevation. The configuration would also lend it self to adjusting for changes in the supply reservoir elevation such as when it may become lower than the entrance of the housing.

[0053] The input elevation can also be adjusted by shortening or lengthening the input end of the device, see Drawing 8 or by changing the angle of the device, see Drawing 9. This may be desired to accommodate optimal entry of the fluid as the level of fluid in the supply reservoir may vary.

[0054] As stated in several of the discussions of the invention detail above, the viscous friction between the surfaces of the housing and baffles with the fluid results in waste. Consequently a surface treatment to minimize friction will be important to address as will the consistency of the geometry of the fluid chamber as the device turns. The discussions of advantage from varying radii and helix pitches above will need to be optimized against these countering losses as both viscous friction and turbulence from changes in geometry will result in efficiency losses.

[0055] At the center of the device along the axial length the baffles may be left open to allow overflow from one chamber to the next. This will provide a self-priming nature to the device. As fluid is entered into the first baffle area, in the event that the torque generated is not adequate to begin rotation of the device when the chamber becomes full, the fluid will then spill over to the subsequent chamber, and so on, until adequate torque is developed. Relatively small seepage holes may be utilized at the circumference to accomplish drainage of the device when it is not in operation.
